OPPORTUNITIES FOR DEVELOPMENT OF ADVANCED LARGE CARGO AIRCRAFT

by Allen H. Whitehead, Jr.

Langley Research Center

SUMMARY

A review and study of the history, current state-of-the-art, and prospects for future cargo aircraft systems indicate that the advantages of air transport relative to surface modes can be characterized by rapid delivery, bridging of geographical barriers, and flexible market response.

Air cargo demand is forecasted to increase in a dynamic manner. Estimates vary between 11 to 16 percent per year between now and the 1990's. Forecasts indicate a fivefold increase in air cargo traffic from 1975 to 1985.

Dedicated, advanced terminals will be required to support the air cargo system of the future. Intermodal containers and handling systems and computerized control and billing may be key ingredients. Farsighted communities such as Coalinga, California, are already studying the potential benefit of serving as a worldwide aerial trade center. Other nations, particularly in Europe, are seriously considering a network of such dedicated freighters.

Preliminary NASA and industry studies indicate that large gains in aircraft payload and fuel efficiency are possible from the application of advanced technologies and configuration concepts. NASA, working in cooperation with elements of DOD and DOT, has defined and proposed a Very Large Aircraft System Technology Program which includes systems studies, R&T, and the determination of the need for individual flight experiments to demonstrate and validate the promises of advanced technology.

The outlook for Air Cargo Aircraft of the future appears bright but will require extensive research and technology activity to realize the forecasted potential.

INTRODUCTION

Compared to the cargo volume transported by the surface modes, air cargo is still in its infancy. Air cargo service was initiated in the United States in the late 1920's with the airmail service, and experienced significant growth during World War II with the transport of critical military supplies. Military airlift accomplished a truly heroic task in the Berlin airlift in 1949. With the advent of efficient high-speed turbine powered aircraft in the late 1950's and 1960's, the future of air cargo appeared bright.

Indeed, airfreight volume generated by United States carriers increased from around 0.3 billion ton-miles in 1950 to 6.0 billion ton-miles in 1974 (ref. 1 and 2). Even with this growth, however, the volume of goods transported by air between the U.S. and Europe in 1973 represented less than 0.5 percent of the total carriage (ref. 3). Some aspects of the current environment are illustrated in figure 1. A significant feature of this transatlantic trade is that of the total $9 billion value of the cargo transported by all modes, the air share is around 25 percent by value. Air carriage is thus already an important factor in the balance of trade. As the photograph suggests in figure 1, considerable improvement can be realized by improved handling techniques.

The purpose of this paper is to provide an assessment of the future of air cargo by analyzing air cargo statistics and trends, by noting air cargo system problems and inefficiencies, by analyzing characteristics of "air-eligible" commodities, and by showing the promise of new technology for future cargo aircraft with significant improvements in costs and efficiency. NASA's proposed program is reviewed which would sponsor the research needed to provide for development of advanced designs by 1985.

The paper will address the following topics:

- Advantages and Disadvantages of Air Cargo Transportation
- Air Cargo Demand Forecasts (Civil and Military)
- Economics of Air Cargo Transport
- Intermodal Demonstration and Community Planning
- Airfreighter Evolution and Integration with Future Terminal Systems
- Proposed NASA Very Large Aircraft Systems Technology Program
These are: (1) rapid delivery, (2) ability to bridge geographical barriers, and (3) flexible market response.

Rapid delivery is required for perishables (lettuce, livestock, etc.) and seasonal commodities (wearing apparel). Cargo mode block speeds for the four conveyances in figure 2 were obtained from ref. 4. Time saved by air transport can reduce costly inventories and warehouse requirements (refs. 5 and 6).

The air system can bridge geographical barriers since aircraft can travel essentially straight-line courses and are not constrained by mountains, streams or oceans. An inherent advantage is elimination of the requirement to change transportation modes at the land-water interface.

A more flexible market response is available since the aircraft speed makes it possible to serve changing market requirements set by consumer demand. A rapid response to volatile seasonal demands, for example, can best be fulfilled by the air mode. The air mode is also adaptable to shifting population centers; in contrast, a rail system involves heavy investment in equipment tied to a fixed network.

Because of its adaptability to varied terrain, air transport has a significant potential for accelerating the growth of developing countries (ref 7). The construction of a network of rail and highways is both expensive and time consuming; airplanes can provide transportation until a complementary ground system can be planned and developed.

The impact of marketing and production errors can be reduced and the cargo is less susceptible to pilferage because of its reduced exposure time.

The principal disadvantages of air are the higher freight rates and the necessity of developing adequate backhaul. In this paper, it will be shown that air cargo can reduce the total distribution cost of many items, even when the air freight rate is significantly higher than the ground mode. A second area involves temporal problems that appear amenable to solution. In that category is included the complex rate structure that is applied to international air transportation. For example, the International Air Transport Association requires unanimous agreement from its carrier members for a commodity rate decision. On the North Atlantic Zone, there are 185 commodity groupings and 19,000 separate rates. To illustrate the confusion, there are different rates for shoes and footwear, cloth and textiles, motorcycle parts and disassembled motorcycles (ref. 3). In today's air cargo network, a large fraction of the system costs are attributed to ground operations. Reductions in costs are possible through more efficient cargo handling, loading, storage and security (refs. 8 and 9). Cargo traffic tends to suffer when accommodated by airlines whose prime focus is on passenger travel; as a result, innovative management and proper equipment are often lacking for air cargo (ref. 10).

**Air Cargo Demand Forecasts**

To maximize the future growth of air cargo most of these problems must be resolved. Projections based on past air cargo traffic are optimistic. The demand for commercial air cargo is increasing as illustrated in figure 3 (ref. 11). The history and forecasts of demand in terms of revenue ton-miles indicates that the current market demand was preceded by an annual growth rate of approximately 13-1/2 percent since 1960. This market is characterized by high value, unplanned, and perishable goods which could maintain an 11 percent growth rate constituting 0.2 percent of the total world trade. As indicated, about half of this volume would continue to be carried as belly cargo on passenger aircraft and half in dedicated freighters.

Attractive new market opportunities exist for expansion into a much broader spectrum of commodities. A significant increase in scheduled airfreight traffic is forecasted to supplement unplanned shipments. Only moderate cost improvements are required to constitute a breakthrough for air cargo operations. These cost reductions can be achieved by improvements in ground operations or by more efficient aircraft designs, or both. In 1970, it was shown from available data that a product value of around $1.00 per pound defined a “threshold” for delineating air-eligible commodities (ref. 8). If reduced air transportation costs allowed that product value to be lowered 25 percent, then an impressive array of major consumer lines would be attractive for air cargo transport (refrigerators, washers, automobiles, etc.). The new market objective shown in figure 3 represents a 16 percent growth rate beyond 1975 and would result in an additional 0.1 percent of the forecasted world trade. This modest stimulation of the market will require a substantial number of new cargo aircraft to meet the projected traffic. For example, the requirement in 1985 equates to about 240 747-F aircraft, or a fewer number of very large aircraft of the multiton gross weight category.

It is well known that the military requires fast-response large airlift capability. This has been demonstrated repeatedly since World War II in Korea, Viet Nam, and several times in the Middle East. Details of one such recent airlift exercise is presented in figure 4 (ref. 12) which deals with the 1973 resupply to Israel during its conflict with the Arab nations. This airlift required 566 total flights over a period of 33 days to transport 22,300 tons over a distance of 6,450 nautical miles, with an intermediate stopover at the Azores. The primary aircraft used in this airlift were the C-141 and C-5A. Other large aircraft such as the Boeing 747 were also utilized but are not included in the statistics of this figure. A wide variety of cargo was transported including pallets containing ammunition, missiles, electronics, etc.; helicopters; cannon; and tanks. Only the C-5A with its massive cargo bay dimensions could carry the M-60 tank and the CH-53 helicopter.
A recent Air Force document (ref. 13) outlines the future requirements for logistic missions that could be served by large freighter aircraft. With existing and ever increasing economic and political pressures such as balance-of-payments and sensitive international political situations, there is a trend to reduce overseas bases and personnel. However, since the Warsaw Pact Nations are planning extremely mobile military force structures, the U.S. must be able to respond quickly by having the capability to move large numbers of troops and materiel to any point in the world. Without adequate intermediate stopover or staging bases, a requirement is seen to exist for aircraft with large payloads and long-range capabilities. One possibility currently under evaluation would consider a common aircraft design for both civil and military airlift. There is even a consideration for shared use of these aircraft under the C.R.A.F. (Civilian Reserve Air Fleet) arrangement, with the military reserving the right to call in these aircraft in a national crisis.

Economics of Air Cargo Transport

An increase in the air freight share of the market is predicated on an increase in carriage of traditional "air-eligible" commodities as well as some penetration into commodities currently transported solely by surface modes. For this reason, shippers, airlines, and aircraft manufacturers need a clear understanding of the economics of cargo transportation as dictated by the market-place.

A comparison of 1973 transportation operating costs and marketing characteristics associated with surface and air modes is presented in figure 5 (ref. 14). The long-haul, low value goods are carried primarily by ships and railroads with costs of 0.8 and 1.8 cents-per-ton-mile, respectively. The short-haul, low and medium value goods are carried primarily by trucks at about 4.9 cents-per-ton-mile. For the air mode the goods are characteristically those of the long-haul, high value category. The early airfreighters had relatively high costs (8- to 9-cents-per-ton-mile) but large improvements have been accomplished by more recent aircraft, such as the Boeing 747 which had a 1973 direct operating cost of approximately 5-cents-per-ton-mile. As will be shown subsequently, it appears that advanced concepts can further reduce the costs, possibly to values below 4-cents-per-ton-mile.

Even though air transportation rates are generally higher than surface rates, other economic factors must be considered before a manufacturer selects the transportation mode for his product. The concept of "Total Distribution Cost" is introduced in figure 6 and is useful in determining the economic value of time saved by air. For a case typical of the appliance industry, the business dollar is divided into manufacturing, marketing, distribution and profit (ref. 15). The distribution costs for surface and air modes are shown and include transportation, inventory and warehousing costs. Because of the speed advantage of the air mode, warehousing and inventory costs are minimized. As the figure illustrates, while air transportation costs are over 20 percent higher, the total distribution costs are reduced, producing a net cost savings of 3 cents. For a company whose distribution system is built around surface transportation, the change to the air mode can be complex. To derive optimum benefit from air carriage, changes may be necessary in warehousing, production, accounting systems, and even changes in organization. The conversion to air distribution may well be an evolutionary process.

A list of the "top-ten" airfreight commodities is presented in figure 7 (ref. 16), and is representative of the items transported by five U.S. Trunk Carriers (United, American, TWA, Eastern, and Delta). Wearing apparel, particularly women's wear, heads the list because of the time-sensitive, "perishable" consumer demand. Another characteristic of clothing that makes it an attractive air commodity is its high value. The high-value item is more able to absorb the higher air freight rates. The top ten commodities shown here represent only 37 percent of the total value of $339 million for these five domestic carriers in 1971. This observation illustrates the wide diversity of products carried by air. Perishables represented only about 15 percent of the revenue produced by the top-ten.

In addition to high-value products, two other product characteristics that lead to "air-eligibility" are fragility and perishability. Television sets are a commodity which are both high-value and fragile. The analysis shown in figure 8 taken from reference 17 illustrates the potential savings in transportation costs for sets manufactured in Japan for distribution through Atlanta, Georgia. The surface mode is characterized by slow-moving conveyances, numerous steps involving considerable handling of the cargo, and highly circuitous routing. Delivery time is three to four months at a per unit cost of $52. Because the air mode reduces this delivery time to four to five days, unit cost drops to $36. This 30 percent savings by air transport is determined by consideration of the capital loss associated with the large inventory tied up in the ground mode "pipeline." Additional savings should also be realized in reduced warehousing costs.

Even for the air mode, considerable additional time and savings could be attained if a "direct-origin-to-destination" pick up and delivery service could be structured to reduce the number of transfers of the cargo between modes. Damage and pilferage would also be reduced. To accomplish this objective, airports would have to be located close to both the supplier and customer or advanced landing systems such as air-cushion systems might be employed to provide an austere or minimum developed field capability near the end points. As will be shown later, such advanced concepts are being studied.

The transport from California to the East Coast of a typical time-sensitive product such as lettuce is illustrated in figure 9 (ref. 18). Presented at the top of the figure is the lettuce freshness condition as a function of transport time, from harvest to delivery, for two values of constant temperature and a temperature variation typical of surface modes. Note that after about ten days, the quality has degraded to a fair condition. Shown at the bottom of the figure are the total distribution costs of
both surface and air modes. Although the air fare is about 40 percent higher, the spoilage is reduced from about 25 percent to 1 percent with a resultant net savings of approximately 30 percent. Not considered in this saving is the additional shelf life of the product provided by the rapid delivery with the air mode.

As a final commodity example, figure 10 presents a photograph of a rather unique air cargo - breeding stock cattle transported by the Flying-Tiger Line (ref. 19). Livestock of all types have been air transported from the U.S. to many diverse markets - such as the Philippines, the Far East, Brazil, Hungary, Spain, and Russia. Most of this traffic in live animals is for breeding. In 1972, Flying-Tiger alone delivered 1,500,000 pounds of livestock to international markets. Direct transportation cost from U.S. to Japan is three times higher than surface rates, but the overall distribution cost is only 5 to 10 percent greater. Three factors have encouraged this type of trade: the efficiency of the modern jet freighter; the improvement in the economies of both developed and developing countries (sirloin brings $11.80 per pound in Japan); and American expertise in raising and breeding livestock.

Intermodal Demonstration and Community Planning

From the type of analysis just considered, it may appear advantageous to ship a certain product by air when the "total cost of distribution" is considered; however, if an efficient ground-support system is lacking, the potential benefits can evaporate. The current problem of excessive cost of ground operations has already been cited (ref. 9). A fresh approach may be needed to reduce these costs which considers the entire transportation system, surface and air. What may be required is an intermodal network dedicated to increasing the total transportation efficiency and capability of the nation, both for military and commercial sectors. A privately-funded joint venture dedicated to defining the most efficient and cost-effective transfer of cargo between modes is underway (ref. 20). The Intermodal Air Cargo Test (INTACT) Project has over 40 participants including aircraft manufacturers, airlines shippers, air forwarders, airports, the Department of Transportation and the U.S. Air Force. The purpose of this project is to prototype and demonstrate a multimodal systems concept employing the U.S. Air Force Lockheed C-5A "Galaxy" aircraft, various land and sea containers, and unique automated handling and loading concepts. Specific objectives are to: (1) establish a basis for determining specifications for cargo handling equipment, (2) define operational interfaces with surface transportation, and (3) develop an operational data base for projection of systems economics and analyses of total cost distribution.

Figures 11 and 12 present aerial and close-up views of recent Project INTACT handling and loading tests. Transcontinental flights and unloading demonstrations have recently been completed between Oakland, California, and Nashville, Tennessee (October 1975). An efficient intermodal air segment linked directly to surface transportation modes is seen as one of the keys to large-volume air cargo operations, so it is critical that this approach be thoroughly evaluated.

Another critical requirement for an efficient air cargo system may be the development of dedicated cargo airports. An example of a farsighted community planning for the future, with prime consideration of aerial trade as a focal point, is illustrated in figure 13 (ref. 21). Coalinga, California, located inland between San Francisco and Los Angeles adjacent to the fertile San Joaquin Valley, has done considerable planning to become a worldwide aerial trade center. With ready access to railroad and interstate highways to facilitate delivery of agricultural goods grown in the valley, the products would be flown to markets all over the world. In this case there is not likely to be a "backhaul" problem since California is a heavy importer of industrial and machine products. The planning and development represented by Coalinga's approach emphasizes the systems analysis methodology in which all elements of the system are considered before committing major resources. As such, Coalinga could serve as the progenitor of tomorrow's aerial trade center. Several references from the transport industry can be cited which allude to the future need for such centers, often referred to as "gateway" centers (ref. 22, for example).

Airfreighter Evolution and Integration with Future Terminal Systems

A brief evolutionary synopsis of airfreighter designs and potential future concepts is presented in figure 14 for both civil and military applications. Although there were earlier aircraft, the real genesis is generally accepted as the Douglas C-47 Skytrain, which had its first flight in 1935. The Douglas C-54 Skymaster, which served both civil and military roles, had its first flight in 1942. The Lockheed C-130 Hercules, a current military work- horse, had its first flight in 1954. The Boeing 707 had its first flight in 1954 and the Douglas DC-8 (series 10) in 1958. The Lockheed C-141 first flew in 1963 and the C-5 in 1968. The Boeing 747 was introduced in 1969. In this 34-year period, the gross weights have increased from 26,000 pounds for the C-47 to nearly 800,000 pounds for the 747 and C-5 aircraft. During this evolution, the direct operating costs have been reduced from approximately 20 cents per ton-mile for the C-54 to approximately 5.4 cents per ton-mile for the B-747 (based on 1975 costs).

A glimpse at what future large cargo aircraft might look like and weigh is illustrated by the distributed-load aircraft concept and a high aspect ratio, laminar-flow control aircraft. The laminar-flow concept is being studied under an Air Force contract.

A measure of the payload and fuel efficiency representative of current wide-body commercial and military aircraft and what may be achieved with advanced concepts such as the span-distributed load design is presented in figure 15 (refs. 24-26). NASA and several aircraft manufacturers are investigating the distributed-load concept in which the payload is

5-4
placed within the wing to partially offset the aerodynamic load. As a result, the net wing bending moment, and thus the structural weight, is significantly reduced. A preliminary NASA analysis (ref. 25) shows the potential benefits and the influence of critical design variables. The application of this concept to the 1990 market is analyzed in reference 26. Critical research and technology is defined in reference 26 that would be required for development of these airplanes in that time period. Other advanced concepts under study include nuclear-powered and hydrogen-fueled configurations. In-flight coupling and decoupling of aircraft and towed systems may provide operational advantages.

The efficiency yardstick of figure 15 is given in the form of revenue-ton-miles per pound of fuel, which is a function of aircraft speed, lift-to-drag ratio, payload-to-gross weight ratio, operating weight-to-gross weight ratio, and specific fuel consumption. The efficiency ratio is plotted as a function of range. The current aircraft have efficiency levels of from two ton-nautical miles per pound of fuel at 2,000 nautical miles to 1.5 at about 7,000 nautical miles. The levels of efficiency estimated to be possible for advanced designs such as the distributed-load flying wing are indicated to be from 70- to 100-percent higher than for current aircraft. As an example to illustrate the benefit of such improved efficiency, the advanced designs could have reduced the number of missions on the Israeli airlift by 77 percent and could have saved 56 percent on total fuel. It should also be noted that the ranges of the advanced aircraft are essentially double that of the current aircraft. Representative estimates of speed, L/D, payload and operating weight ratios are presented in tabular form. A comparison of these values indicates that, relative to current aircraft, the advanced aircraft would probably be somewhat slower because of its thicker airfoil, would have an aerodynamic efficiency about 30 percent higher, have a payload ratio 2.3 times higher, and have an operating weight ratio 50 percent lower.

A multimission air freighter concept which employs a very thick unswept wing (thickness of approximately 20 percent of the wing chord) is shown in figure 16. This version of the distributed-load concept would probably require the small horizontal tail to provide acceptable stability and control. The straight wing configuration utilizes constant-thickness wing sections which would reduce the tooling and manufacturing costs by reducing the number of "part cards" (a part card is needed to identify each unique element of the aircraft structure). Preliminary estimates indicate that the number of part cards for distributed load aircraft might be reduced to one-fifth the number required for typical wide-body aircraft.

Also shown in figure 16 is a cargo loading system to efficiently handle inter-modal containers delivered by truck. The loading platform would incorporate multiple-rollers or an advanced air-bearing system demonstrated in a preliminary design concept in Project INTACT (ref. 20).

A unique application of the distributed load concept is depicted in figure 17. This low aspect-ratio design could operate in ground effect and could take off or land on water or unprepared terrain by vectoring the thrust from the forward mounted engines below the wing. Whereas the aerodynamic efficiency of this design is limited, the vehicle promises an exceptionally low structural weight fraction. The fuselage can provide space for passengers, which are difficult to accommodate in flying wing vehicles.

Swept wing versions of the distributed load concept (figure 18) may not require separate horizontal stabilizing and control surfaces since the wing control surfaces, which would act as elevons, have greater lever arms than for the unswept version. Such configurations approach "flying-wings" with attendant higher Mach number capability and higher aerodynamic efficiencies. The pods on this conceptual design could be used for fuel or even passengers; in the full-scale version, these pods would be equivalent in length and diameter to that of a B-737 fuselage.

Another swept wing design proposed by the Lockheed-Georgia Company is designed to house outsized cargo in a fuselage section (figure 19). Standard 8'x8' containers would be carried in the wing, but up to 23 percent of the payload could be carried in the center body. Then canards are required to provide adequate stability to counteract the fuselage weight. Maintaining the outsized cargo capability in this design concept degrades the payload fraction (payload divided by gross weight) somewhat because of the empennage weight and the concentrated loads at the wing root. There are also problems in loading the aircraft efficiently. The outsized cargo capability may be essential, however, for the military airlift requirement, and this design feature is only one of several potential compromises that may be required in arriving at a common design to satisfy both civil and military cargo requirements.

Other countries, particularly Russia and Germany, are actively planning and even flying prototypes of large aircraft concepts (refs. 27 and 28).

A large fraction of current operating costs is associated with ground operations (ref. 9). A terminal area concept for the future must be designed to facilitate cargo disposition at minimum overall cost. A dedicated cargo terminal concept which could meet this objective is depicted in figure 20 (ref. 29).

Such a system would be fully mechanized and computer-controlled, with emphasis on high volume, high-speed processing and minimum manpower. Cargo is delivered by truck, sorted and unitized for efficient air shipment, then the palletized or containerized units are sequenced for optimum loading onto the proper aircraft. These operations would all be computer-controlled, including the mechanical operations. The computer system would automatically weigh and price each item, provide the proper sequencing, and bill the customer. The computer could be queried for determining the status of any item in the system.
and to provide data and data analysis for management. The reduced operating costs and efficiencies attributed to higher level of mechanization must be traded off against the increased investment cost of such a system.

The proposed advanced freighters such as depicted in figures 16 through 19 would not be adequately supported by today’s air cargo handling system because of their massive payload capacities and large wing spans. The development of efficient cargo terminals and cargo handling systems is an essential ingredient for optimizing tomorrow’s air cargo system.

Proposed NASA Very Large Aircraft Systems Technology Program

NASA, in cooperation with the Departments of Defense and Transportation, and the National Science Foundation, is currently involved in a number of activities that are expected to evolve into a Very Large Aircraft Systems Technology Program. Some of the major elements of such a program are shown in figures 21 and 22 with specific examples of various disciplinary activities illustrated in figures 23 through 28.

The program elements are illustrated pictorially in figure 21 and are shown in a proposed schedule in figure 22. These elements consist of systems and design studies, advanced concept development, research and technology investigations, simulation, and the determination of the need for possible flight experiments or demonstration. Currently, a technology impact assessment of large cargo aircraft is under way with Gellman Research Associates under joint sponsorship of the National Science Foundation and NASA. Preliminary survey systems studies of advanced concepts and capabilities are under way with Boeing, Douglas, and Lockheed Aircraft Companies. Market systems studies are scheduled to be initiated in the near future.

The necessary research and technology elements, some of which are illustrated pictorially in figure 21, include advanced concept development, composite structures, landing systems, flight-controls, propulsive lift, and thick airfoil analysis and experimental development.

Advanced transports will make extensive use of composite materials to reduce structural weight—about 40 percent of the conventional metal structure might be replaced by composites. An illustration of the Advanced Composites Program, under the direction of NASA Langley is presented in figure 23. A recent survey of the NASA program is found in reference 30. Advanced composites are made from thin, high strength fibers such as special glasses, graphite, and boron imbedded in a plastic or, in some cases, metal matrix material. The program will provide design, durability, and maintainability data for composite materials in airline service. This figure shows several pieces of secondary structure that are being evaluated on commercial transports. Some of the parts have been flying for more than 4000 hours and are functioning better than the part they replaced. The sketch at the lower right shows the next step in NASA Langley’s Advanced Composites Program. The main load-carrying sections of the wings will be constructed of composites and installed on a commercial transport beginning in the latter part of the decade.

Figure 24 presents a photograph of a 1/90th scale model of a NASA span-distributed load configuration in the Langley 7- by 10-foot wind tunnel. The purpose of these tests is to provide preliminary performance, stability and control characteristics on three-dimensional models incorporating very thick airfoils (streamwise t/c = 0.20), and flying wing concepts. This model is representative of a concept that would have a span of approximately 375 feet, and payload of over a million pounds, and a gross weight of approximately 2.5 million pounds. It would employ eight high bypass ratio engines (BPR = 10), each having 75,000-pound thrust at sea level.

The iterative process employed in the design of advanced thick airfoils is illustrated in figure 25. Analytic methods, depicted by use of the high-speed computer, account for both compressibility and boundary-layer effects and are used to parametrically determine the best airfoil sections to meet design constraints. Typical results such as pressure coefficient and drag which characterize the airfoil are shown in the figure. Two-dimensional wind-tunnel tests are then conducted to verify the analytic results and to further optimize the performance. For thick airfoils, it is important to test at as high a test Reynolds number as possible in order to adequately simulate flight conditions. The general contour of a supercritical airfoil section is volumetrically efficient for packaging multiple containers of square cross section. These airfoils have a large leading edge radius and maintain near maximum thickness for a large part of the chord. Because of the high aft camber, however, these sections exhibit large negative zero-lift pitching moments; trimming these could result in a greater loss in lift and/or a larger empennage than would be required for a conventional airfoil section. Recent surveys of the NASA Langley program in airfoil design are presented in references 31 and 32.

The use of active controls on a large aircraft is illustrated in figure 26. Active Controls Technology (ACT) is the extension of automatic control techniques beyond the usual stability and control functions. The advantages offered by ACT stem from the removal of limitations imposed by the traditional passive methods associated with a fixed-geometry configuration. ACT concepts involve continuously operating control surfaces in one or more feedback loops. Digital computers and fly-by-wire systems would be an integral part of the ACT system (refs. 33 and 34). Active controls may be utilized to reduce trim drag through the use of relaxed static stability (rearward c.g. location) resulting in reduced tail sizes. Wing weight can be reduced with active controls through tailoring the wing span-load distribution to reduce the wing bending moments experienced in maneuvers and gusts. Further gains may be possible through flutter suppression, but this application represents a greater dependence on ACT for safety-of-flight. Finally, active controls can provide
The key elements for future expansion of air cargo are summarized in figure 29. A review and study of market response with the air mode can often provide a net savings by air. Foreseeable advances in large aircraft development offer even greater profit potential by increasing the payload ton-miles per pound of fuel. Preliminary NASA and industry studies indicate that large gains in aircraft payload and fuel efficiencies and reductions in development and operational costs are possible from the development and application of innovative advanced technologies and configuration concepts. NASA, in cooperation with elements of DOD and DOT, has work under way and has defined a Very Large Aircraft Systems Technology Program which includes systems studies, research and technology investigations, and a determination of the need for critical flight experiments.

The outlook for Air Cargo Aircraft of the future appears bright and the extensive R&T activity required to realize the forecasted potential has begun.

CONCLUDING REMARKS

The key elements for future expansion of air cargo are summarized in figure 29. A review and study of the history, current state-of-the-art, and future prospects for cargo aircraft systems indicates that three of the major advantages of air cargo are rapid delivery, the ability to bridge geographical boundaries, and the capability to provide a flexible market response. The main disadvantage is a higher transportation cost relative to surface modes. However, when other distribution elements are considered such as warehouse, inventory, and spoilage costs, the reduction in those factors associated with the air mode can often provide a net savings by air. Foreseeable advances in large aircraft development offer even greater profit potential by increasing the payload ton-miles per pound of fuel.

Air cargo demand is forecasted to increase in a dynamic manner with estimates of ton-mile growth varying from 11 to 16 percent per year between 1975 and 1985, the higher rate equating to an approximate fivefold increase (15 to 75 billion ton-miles). Stimulation of this demand will result from the development of advanced cargo systems incorporating both innovative and efficient cargo airplanes and dedicated cargo terminals. Consideration of future aircargo systems requirements is being pursued in Project INTACT (Intermodal Air Cargo Test), which is a privately funded joint venture involving over forty participants representing aircraft manufacturers, airlines, air forwarders, airports, DOT, and the Air Force. The community of Coalinga, California, is considering plans which would transform the city to a worldwide aerial trade center, exporting produce from the fertile San Joaquin Valley.

CONCLUDING REMARKS

The key elements for future expansion of air cargo are summarized in figure 29. A review and study of the history, current state-of-the-art, and future prospects for cargo aircraft systems indicates that three of the major advantages of air cargo are rapid delivery, the ability to bridge geographical boundaries, and the capability to provide a flexible market response. The main disadvantage is a higher transportation cost relative to surface modes. However, when other distribution elements are considered such as warehouse, inventory, and spoilage costs, the reduction in those factors associated with the air mode can often provide a net savings by air. Foreseeable advances in large aircraft development offer even greater profit potential by increasing the payload ton-miles per pound of fuel.

Air cargo demand is forecasted to increase in a dynamic manner with estimates of ton-mile growth varying from 11 to 16 percent per year between 1975 and 1985, the higher rate equating to an approximate fivefold increase (15 to 75 billion ton-miles). Stimulation of this demand will result from the development of advanced cargo systems incorporating both innovative and efficient cargo airplanes and dedicated cargo terminals. Consideration of future aircargo systems requirements is being pursued in Project INTACT (Intermodal Air Cargo Test), which is a privately funded joint venture involving over forty participants representing aircraft manufacturers, airlines, air forwarders, airports, DOT, and the Air Force. The community of Coalinga, California, is considering plans which would transform the city to a worldwide aerial trade center, exporting produce from the fertile San Joaquin Valley.
